## **FOREWORD**

Corals belonging to the genus *Porites* exhibit one of the most simple growth forms within a class of organisms which is second only to sponges in its primitive simplicity of body structure. One might think that this, together with the facts that growth is one of the most fundamental of biological processes, and corals are among the best studied of all reef animals, would mean that growth in *Porites* was well understood and that it could all be summarised in just a few pages. Janice Lough and Dave Barnes have made careers out of demonstrating the fallacy of this assumption. In this CRC report Lough and Barnes gather together the basic growth data for over 350 coral colonies scattered between PNG and the southern GBR. This is an extraordinary data set and represents a resource to other coral growth researchers which is often not available in such rich detail due to the constraints imposed by publishers of international science journals.

By virtue of the great age which *Porites* can attain, and their tendency to lay down alternate bands of high and low density skeleton, these corals have the potential to reveal an incredible amount of information about past environmental conditions. Unlocking the information contained in skeletal records requires a good understanding of how growth characteristics can change between colonies at scales from an individual reef to half a continent. The extensive data set analysed in this report indicates that growth characteristics can change significantly from north to south along the GBR and across the continental shelf. They also demonstrate the importance of temperature in determining extension and calcification rates. This knowledge is essential when extracting long-term trend data on coral health and climatic variables from small coral samples at different locations - a situation many other researchers find themselves in.

The larger research effort by Barnes & Lough, of which this report is just a small part, is making a significant contribution to our understanding of how coral are affected by long-term climatic trends, and geographic location. This information is vital to managers who need to predict how corals will react to and recover from perturbations at smaller scales caused by human activity. In essence their data provide the kind of baseline needed to put modern activities and impacts into context.

## EXECUTIVE SUMMARY

Annual density banding patterns in massive coral skeletons provide a means to “retrospectively monitor” growth characteristics of massive corals on the Great Barrier Reef (GBR). We have analysed annual growth characteristics for colonies of the major reef-building genus, *Porites*, collected from shallow water (< 5 m) over 14° of latitude (1500 km), and from the coast to 200 km offshore. Growth characteristics have been extracted for 357 colonies and 35 cores. This provides information about geographic variation in the performance of this major reef-building coral and the natural range in *Porites* performance over space and time. This provides baseline data against which the significance of observed or suspected natural and unnatural changes in reef environments can be assessed.

Major findings of this study of colonies of *Porites* from shallow water are:

- ?? Growth characteristics of *Porites* colonies from the GBR show a high degree of variability in space and time. Despite this variability there is evidence of broad scale geographic patterns.
- ?? Some growth characteristics varied significantly with latitude: extension and calcification were lowest and effective tissue layer thickness was highest in the southern GBR
- ?? Linear extension and calcification were significantly and directly correlated with latitudinal variations in average sea surface temperature.
- ?? Linear extension and calcification were not linked with latitudinal variations in solar radiation, rainfall, river flow or tropical cyclone activity. Lack of linkage with solar radiation arose because these shallow water *Porites* would have been light saturated through most of the day.
- ?? Some growth characteristics varied significantly from inshore to offshore sites: effective tissue layer thickness and average skeletal density were highest at offshore sites and lowest at inshore sites whilst extension was highest at inshore and lowest at offshore sites.
- ?? There were significant differences in some growth characteristics with colony size and age: tissue layer thickness, effective tissue layer thickness and annual extension were significantly higher and average skeletal density was significantly lower in the larger and older coral cores compared with the smaller and younger coral colonies.
- ?? Some growth characteristics varied significantly from the top to the sides of colonies: tissue layer thickness, high-low density, extension and calcification were significantly higher when measured along the most vertical colony growth axis compared with the near horizontal track (at the side) of the colony.

- ?? Massive *Porites* colonies should be identified to species level before they are used in recovery of environmental information. *Porites solida* is significantly denser than the 5 other species of massive *Porites* from the GBR. *Porites mayeri* tends to be the least dense species.
- ?? Data reported here fit well with the Townsville model of *Porites* growth in which annual density variations are due to thickening of skeletal elements below the outside surface of colonies.

## INTRODUCTION

One of the problems in studying, assessing and, perhaps, managing change in a marine ecosystem, such as the Great Barrier Reef (GBR), is lack of knowledge about the natural range of spatial and temporal variability expressed by its constituent organisms. Detailed observations and measurements of the GBR, as with other coral reef systems, began only about 20 years ago. Systematic monitoring programs have been instigated only within the past decade. Any trends or variations observed within recent decades may be due to natural environmental change or to natural variations in the system, or they may be responses to increasing anthropogenic stress. Unnatural change in reef environments will be recognised with certainty only when it can be distinguished from natural variability. Climatic change and human activities in the near-shore zone have raised concerns for coral reefs (see, for example, Brown & Howard, 1985; Hopley, 1988; Ginsburg, 1994; Wilkinson & Buddemeier, 1994). Such concerns have highlighted the importance of making use of the histories of coral growth stored in massive corals (eg D'Elia *et al.*, 1991; Smith & Buddemeier, 1992). The discovery of annual growth bands in massive corals as revealed by X-radiography (Knutson *et al.*, 1972) "...rendered almost trivial the previous unsolved problem of measuring long-term growth rates and growth histories retrospectively..." (Buddemeier & Kinzie, 1976). Such records allow us to establish the "expected" performance of massive corals over time and across different environments. Such baseline data makes it possible to distinguish natural variability from unnatural change. Coral growth records, which can extend back 100s of years, provide information about how massive corals have responded to natural and unnatural changes in their environment.

Previous studies of *Porites* growth on the GBR have shown that growth characteristics measured from density banding patterns vary along environmental gradients with change in environment and over time (see Barnes & Lough, 1996; Lough & Barnes, 1997, for recent reviews). Isdale (1983) found that linear extension of *Porites* decreased from inshore to offshore locations in the central and northern regions of the GBR and was highest in the more northerly regions. Risk & Sammarco (1991) found that skeletal density in *Porites* increased with distance from shore in the central GBR and suggested this reflected higher calcification rates at less turbid, more turbulent, offshore reef sites. Lough & Barnes (1992) measured both extension and density in *Porites* along an inshore-offshore transect in the central GBR (~18.3°S). The transect comprised Pandora, Rib and Myrmidon Reefs which are 16, 60 and 120 km from shore, respectively. They found that annual calcification, the product of annual extension and average annual density (see Chalker *et al.*, 1985), decreased with distance from

shore and was distinctly lower at Myrmidon Reef, which lies at the margin of the continental shelf.

In this report we provide average growth characteristics for massive colonies of the common reef-building coral *Porites* from the length and breadth of the GBR. We report on 264 small (0.1 to 0.5m) *Porites* colonies from 31 reefs on the GBR (Fig. 1; Table 1) and 35 cores obtained from very large (1.6 to 8.0m) *Porites* colonies (Fig. 2; Table 2). These data are supplemented by growth characteristics for (a) 93 *Porites* colonies from the fringing reef at Misima Island, Papua New Guinea (PNG; Fig. 3, Table 1), (b) 2 modern and 6 recent (6-8,000 year-old) *Porites* colonies from the Huon Peninsula, PNG (Table 1) and (c) 7 cores from very large *Porites* colonies from near Darwin, PNG and Tahiti (Table 2). Coral cores were collected by Dr P.J. Isdale of Australian Institute of Marine Science (AIMS). Coral colonies from Misima Island were collected by Misima Mines Pty. Ltd. and analysed as part of their Environmental Monitoring Program. Dr J. Pandolfi (then at AIMS) collected the corals from the Huon Peninsula. Mr Andy Steven (then at Great Barrier Reef Marine Park Authority) collected the corals from One Tree Island in the extreme south of the GBR as part of his PhD work at James Cook University.

This report provides information about geographic variations in the performance of massive *Porites*, a major reef-building coral in the GBR region. Species of massive *Porites* are most commonly used in coral environmental record studies. Around 40% of all coral record papers report studies with *Porites*. The next most commonly used genus is the Atlantic coral, *Montastrea annularis*. Around 20% of all coral record papers report studies with *Montastrea annularis* (*Porites* does not form massive colonies in the Atlantic).

This study was aimed at gaining better understanding of the geographical variations in growth performance of *Porites* in the GBR region. Variation of *Porites* growth on the GBR over several centuries has been reported previously (Lough & Barnes, 1997). Most importantly, this study was intended to provide a baseline against which to assess variations in the performance of *Porites* on the GBR (and, perhaps, elsewhere), and against which to judge any apparent anomalies and changes in the performance of *Porites*.

This report brings together all measurements of *Porites* growth characteristics from the GBR region and consists of:

1. A description of the methods used to obtain average annual growth characteristics from the density banding patterns in massive corals.
2. A summary of environmental conditions along the length of the GBR.
3. A summary of average coral growth characteristics by region along the GBR.

Appendix A provides detailed information about collection of coral colonies.

Appendix B gives average growth characteristics for each of the colonies (n=365).

This report is supplemented by a database containing all annually dated growth measurements for the colonies and cores, available, on request, from the authors.

## MATERIALS AND METHODS

### Coral colonies

Whole colonies of *Porites*, between ~0.2 and 0.5 m in height, were collected from depths of 3-5 m relative to mean low water spring tide levels from various reefs on the Great Barrier Reef (GBR; Fig. 1, Table 1; Lough and Barnes, 1992). We tried to collect 3 colonies of each of the 5 massive species of *Porites* at each site. Between 6 and 15 colonies were collected from each site. This collection was supplemented by 93 colonies of massive *Porites* collected from Misima Island, Papua New Guinea (PNG; Lough *et al.*, 1995; Barnes & Lough, in press). Andy Steven (then at the Great Barrier Reef Marine Park Authority) collected 10 small colonies of *P. lobata* (0.09-0.16 m high) from One Tree Island (Steven, 1998; in prep.). John Pandolfi (then at AIMS) collected 2 living and 6 recent (estimated to be 6-8000 years old) *Porites* colonies from the Huon Peninsula. Further details of these collections are given in Appendix A. Andy Steven identified colonies from One Tree Island; all other colonies were identified to species by Monty Devereux (AIMS).

### Coral cores

The Australian Institute of Marine Science began collecting cores from very large massive colonies of *Porites* in the early 1980s. An underwater pneumatic drilling rig (Isdale & Daniel, 1989) was used to extract cores in 700-800 mm lengths. Holes left in colonies were sealed with a concrete plug. Early coral cores were 50 mm in diameter; later cores were 90 mm in diameter. Once extracted, cores-lengths were washed in fresh water, dried in trays,

coded and transported to the laboratory. Core-lengths were then mounted and 6-7 mm thick slices were sawn from close to their central axes. As far as possible, core-lengths comprising a single core were aligned such that slices were removed from the same axis. Normally we were not able to identify cores to species level because of damage to the calicular surface caused during drilling. Data is presented here for 35 cores from the GBR (Fig. 2; Table 2) supplemented by 7 *Porites* coral cores collected from northern Australia, near PNG and Tahiti (see "Other sites" in Table 2).

#### Coral sample preparation and density measurements

Coral colonies were cut in half with a chain saw fitted with a masonry blade. Fresh water was played onto the blade during cutting. One half of the colony was placed on the moveable bed of a circular masonry saw and at least two, 6-7 mm thick slices were removed from the centre. The circular saw blade was lubricated by fresh water. With the exception of colonies from the central transect of the GBR, slices represented the colony diameter. Colonies from the central transect were too big to pass through the saw which was then available. These colonies were first cut into quarters and the slices represented half the colony diameter (see Lough & Barnes, 1990a).

Colony slices and cores slices were air-dried and X-radiographed. An X-ray positive was used to identify the position of tracks along which density was to be measured. Tracks were positioned along regions with the best-defined density banding pattern. We avoided imperfections in the slices due to, for instance, boring organisms. We also aligned the tracks so that they followed, as far as possible, an individual corallite fan - thus minimizing density variations between and across corallite fans. Three densitometric tracks were selected on slices from the 254 colonies we collected from the GBR (ie, all GBR colonies, excluding those collected by Andy Steven from One Tree Island). All tracks started close to the origin of the colony. Two of the tracks were usually close to the vertical (upward) growth axis of the colony. A third track was directed towards the side of the colony, usually along a horizontal or nearly horizontal growth axis (see Lough & Barnes, 1990a, 1992). Measurements were made along 1-2 more or less vertical tracks on the small colonies from One Tree Island. Two tracks close to the vertical growth axis were measured on the colonies from Misima Island. A single track was measured down the length of coral cores.

Density was measured along each track using a gamma densitometer. The density measurements were based on the attenuation, through the thickness of the coral slice, of a beam of gamma photons (see Lough & Barnes, 1992 for a full description of the measurement system). Density measurements were made using a 4 mm diameter collimated beam (see

Lough & Barnes, 1990b) at 0.254 mm intervals along the selected track. A data series of absolute density vs. distance along the slice was generated for each track (see example in Fig. 4).

The corals were not bleached and the tissue formed a dark band at the outside of each skeletal slice. The thickness of this band was measured where it was crossed by a densitometric track. This provided a measure of the depth to which skeleton was occupied by tissue (Barnes & Lough, 1992). This measurement is known as the thickness of the tissue layer (*ttl*).

#### Dating and extraction of coral density variables

In dating the annual density bands we have assumed that high density bands form in (austral) summer and low density bands form in winter (see Lough & Barnes, 1990a, 1992). Based on this assumption and the date of collection of a particular sample, high density bands were successively dated backwards from the outside edge of the coral colony or core. The complex 3-dimensional architecture of the coral skeleton often distorts and confuses the density image presented by X-radiography and the density signal resulting from gamma densitometry (Barnes *et al.*, 1989; Barnes & Lough, 1990; Lough & Barnes, 1992). This sometimes can introduce uncertainties into dating of density peaks. A subjective index was used to describe the confidence in dating each specimen (see Lough & Barnes, 1992). A value of 1 indicates reasonable confidence that all annual growth layers were identified and correctly dated. A value of 2 indicates general confidence about dating while recognizing that problems may have occurred in 1 or 2 years. A value of 3 indicates low confidence in dating because of difficulties with identifying several to many of the annual growth bands. We present and analyse here only coral colonies with dating categories 1 and 2. In Appendix B colonies assigned to dating category 1 are flagged by \*; all other colonies are assigned to category 2.

Ten variables were obtained from each density track and dated year (more detail is given in Fig. 2, Lough & Barnes, 1992):

1. annual average density ( $A_{den}$ ; g.cm<sup>-3</sup>.yr<sup>-1</sup>)
2. high density ( $H_{den}$ ; g.cm<sup>-3</sup>.yr<sup>-1</sup>)
3. low density ( $L_{den}$ ; g.cm<sup>-3</sup>.yr<sup>-1</sup>)
4. annual density range; high minus low density ( $H-L_{den}$ ; g.cm<sup>-3</sup>.yr<sup>-1</sup>)
5. annual extension rate measured as the distance between successive high density maxima ( $H-H_{dist}$ ; mm.yr<sup>-1</sup>)
6. extension from high density maximum to low density minimum ( $H-L_{dist}$ ; mm.yr<sup>-1</sup>)<sup>‡</sup>
7. extension from low density minimum to high density maximum ( $L-H_{dist}$ ; mm.yr<sup>-1</sup>)<sup>\*</sup>
8. annual calcification rate - the mass of CaCO<sub>3</sub> deposited per unit area per year – the product of average annual density and annual extension ( $calcn$ ; g.cm<sup>-2</sup>.yr<sup>-1</sup>).
9. depth of the living tissue layer ( $ttl$ ; mm)<sup>†</sup>.
10. effective tissue layer thickness =  $ttl/H-H_{dist} = \text{mm/mm.yr}^{-1} = \text{yr}$ ; see Taylor *et al.*, 1993  
( $ettl$ ; yr,<sup>†</sup>).

#### Rejection of coral specimens

Samples were rejected when it proved difficult to extract reliable density variables because densitometer traces could not be dated with confidence (ie category 3 dating). Colonies were also rejected at earlier stages of analysis. For example, examination of the X-ray positives sometimes led to a sample being rejected because the annual banding pattern was not clearly displayed due to, for example, bore holes, convolutions in the growth surface, etc. (see Fig. 1 in Lough & Barnes, 1992). Including colonies assigned to category 3 dating, we rejected 18% of the 444 colonies collected.

---

<sup>‡</sup> Assuming high density forms in summer and low density in winter,  $H-L_{dist}$  represents the distance grown from the winter to the following summer (see Fig. 2 in Lough & Barnes, 1992).

<sup>\*</sup> Assuming high density forms in summer and low density in winter  $L-H_{dist}$  represents the distance grown from the summer to the following winter (see Fig. 2 in Lough & Barnes, 1992).

<sup>†</sup>  $ttl$  and  $ettl$  are based upon the thickness of the tissue layer at the time that the colonies were collected. It is not possible to determine tissue thickness across the length of the density record.

### Identification of coral specimens

AIMS uses the following labeling codes for coral cores:

**XXX YY Z**      where XXX is 3 letter reef code  
YY is 2 digit coral colony (bommie) number  
Z is 1 letter identification for different cores from same coral

(eg PAN 04 B is a core from Pandora Reef, colony number 04, core B; see Table 2)

AIMS uses the following labeling codes for coral colonies:

**XXX B YY**      where XXX is 3 letter reef code  
YY is 2 digit colony (bommie) number  
(eg DOU B06 is colony 06 from Double Island).

Where more than 1 slice is taken from a core or colony, the label *S<sub>n</sub>* is added to the code to indicate the slice number (eg S2 indicates slice 2). Slices are numbered sequentially from the first slice removed.

### Environmental data

Monthly sea surface temperatures (SSTs) for 1° squares were obtained from the Integrated Global Ocean Services System (IGOSS) data set of the National Meteorological Center (NMC; available from <http://ingrid.ldgo.columbia.edu>). These are a blend of data from ship, buoy and bias-corrected satellite measurements. Average monthly mean SSTs were extracted for the period 1982-1997 for fourteen, 1° squares covering the length of the GBR from 10.5°S, 143.5°E to 23.5°S, 151.5°E.

Monthly mean (1949-1979 base period) values of incoming solar radiation for 2° squares were obtained from the Global Ocean Surface Temperature Atlas Plus (GOSTAPPlus). These values are calculated as follows (see Bottomley *et al.*, 1990, p.11):

$$\text{Incoming solar radiation} = Q_o (1 - 0.62C + 0.0019?) (1-A)$$

where  $Q_o$       = total radiation received at surface in  $\text{W.m}^{-2}$  when sky is clear  
 $C$       = cloud cover in tenths (as observed by “ships of opportunity”)  
?      = solar noon altitude  
 $A$       = oceanic albedo

Monthly mean values of incoming solar radiation were obtained for the seven,  $2^{\circ}$  latitude by  $4^{\circ}$  longitude blocks along the GBR from 10-12°S, 140-144°E to 22-24°S, 150-154°E.

Monthly rainfall totals were obtained from the Australian Bureau of Meteorology for stations along the Queensland coast. Data from several stations were combined to form four coastal district rainfall series centred on the following latitudes: Region 1 ~12°S, Region 2 ~17°S, Region 3 ~20°S and Region 4 ~24°S (see Lough, 1994, 1998).

Estimates of the annual volume of river flow from the Queensland drainage basins entering the GBR were obtained from the Department of Natural Resources, Queensland. Estimates of annual volume of flow were summed by  $1^{\circ}$  latitude bands along the Queensland coast.

Details of tropical cyclone activity were obtained from Lourens (1981) for the period up to 1980 and from the Australian Meteorological Magazine for more recent years. A tropical cyclone in the Australian region is defined when average wind speeds associated with a low pressure centre are at least  $63\text{km.hr}^{-1}$ . Each day while a tropical cyclone remains within a specified area is defined as a tropical cyclone day. Counts were made for each year, over the period 1958-1992, of the total number of tropical cyclones and total number of tropical cyclone days for each  $2^{\circ}$  latitude band, between 10-12°S and 22-24°S, and extending 220km out from the coast, (see Lough, 1994, 1998).

### Analyses

The mean and standard deviation were used to describe coral growth characteristics and their variability. Growth characteristics for coral colonies were averaged for a common period for each collection. These base periods, varying in length from 10-17 years, are identified in Appendix B. The earliest start year for the base periods is 1972 for the southern GBR collection and the latest end year is 1995 for colonies from One-Tree Island. For the analysis of the 250 similar-sized colonies on the GBR, the base periods for the 5 different collections have at least 8 years in common. Analyses of growth characteristics are based on averages over the respective base periods of 10-17 years in length – mainly from the mid-1970s to late 1980s. It is unlikely that these minor differences in base periods would significantly bias the analyses of spatial variations. Growth characteristics for the coral cores were averaged for the common period 1934-1982. Comparisons of growth characteristics within and between reef locations were made using ANOVA. The correlation coefficient was used to assess the degree of similarity between different growth variables and between coral growth variables and environmental variables.

## RESULTS

### Environmental conditions along the GBR

*Porites* growth characteristics have been obtained from colonies collected or sampled along the length ( $10^{\circ}$ - $24^{\circ}$  S) of the Great Barrier Reef (GBR). Variations in average climatic conditions along the length of the GBR provide a background against which to assess spatial variations in coral growth (further climate information is given by Lough (1994, 1998).

Sea surface temperatures (SSTs) on the GBR ( $10^{\circ}$ - $24^{\circ}$  S) vary seasonally from  $>29^{\circ}$ C to  $<21^{\circ}$ C (Fig. 5a). North of  $\sim 20^{\circ}$ S, average annual SSTs are  $>26^{\circ}$ C and the annual range is  $<5^{\circ}$ C. South of  $\sim 20^{\circ}$ S, average annual SSTs are  $< 25^{\circ}$ C and the annual range is  $>6^{\circ}$ C. Incoming solar radiation on the GBR varies seasonally from  $>260 \text{ W.m}^{-2}$  to  $<160 \text{ W.m}^{-2}$  (Fig. 6a). Average annual solar radiation is highest south of  $\sim 18^{\circ}$ S ( $>200 \text{ W.m}^{-2}$ , Fig. 6b) because, further north, solar radiation is modulated by increased cloud cover during the summer wet season. The seasonal maximum in solar radiation occurs in October-December. Annual rainfall is concentrated into the summer half of the year (October to March) in all regions adjacent to the GBR (Fig. 7). Rainfall in all regions exhibits very high inter-annual variability (illustrated by the large decile ranges in Fig. 7). Rainfall is highest in coastal regions north of  $\sim 20^{\circ}$ S. Annual freshwater input to the GBR from rivers is concentrated in the belt from  $\sim 17$ - $20^{\circ}$ S (Fig. 8). As with rainfall, year-to-year variability of river flow is extremely high. Furnas *et al.* (1997) estimated that average freshwater discharge into the GBR was  $\sim 42 \text{ km}^3 \cdot \text{yr}^{-1}$  over the period 1958-1992. The maximum discharge over this period was estimated to be  $\sim 120 \text{ km}^3 \cdot \text{yr}^{-1}$  in 1974; the minimum was estimated to be  $\sim 12 \text{ km}^3 \cdot \text{yr}^{-1}$  in 1987. Waves and winds associated with tropical cyclones are another source of disturbance to reef communities (eg Massel & Done, 1993; Done, 1997). On average, the amount of tropical cyclone activity along the GBR peaks in the belt  $16$ - $18^{\circ}$  S (Fig. 9; see Puotinen *et al.*, 1997 for more details of tropical cyclone movements along the GBR).

### Average growth characteristics of *Porites*

Analyses of average *Porites* growth characteristics have been presented previously for 25 colonies from the central GBR transect (Lough & Barnes, 1992), for 35 long cores of the GBR (Lough & Barnes, 1997) and for 93 colonies from Misima Island (Lough *et al.*, 1995; Barnes & Lough, in press). The *Porites* colonies from Misima Island were collected to test whether a change in the environment due to mining activities altered *Porites* growth characteristics. Extension, density and calcification of these colonies showed no significant effect that could be associated with mining activities (Barnes & Lough, in press). Tissue layer thickness was the only variable that showed a change that could be linked with proximity to mining activities. Thus, it seemed reasonable to include this data set in the

analysis of geographical patterns of *Porites* growth. Here we present analyses of *Porites* growth characteristics for:

1. 250 similar-sized *Porites* colonies collected along the GBR. These comprise the 139 colonies from the northern, central and southern transects, 90 colonies from the Cairns-Cape Melville transect and 21 colonies from Mission Beach.
2. 357 *Porites* colonies collected over latitudes from Misima Island, PNG, in the north to One-Tree Island in the south. These comprise the 250 colonies mentioned above (1), 93 colonies from Misima Island (Lough *et al.*, 1995; Barnes & Lough, in press), 4 colonies from Ashmore Reef and 10 colonies from One-Tree Island (see Table 1).
3. 35 cores extracted from very large (>1.6 m high) *Porites* colonies from locations covering the length of the GBR (Lough & Barnes, 1997).

Average growth characteristics for all 357 coral colonies, summarized by reef (or transect for Misima Island) are presented in Table 3. Equivalent data for the 35 coral cores are presented in Table 4.

#### Average growth characteristics of 250 similar-sized *Porites* colonies on the GBR

##### *Variation with species (250 colonies)*

Five species of *Porites* were represented in the 250 colonies; *P. lobata*, *P. lutea*, *P. australiensis*, *P. mayeri* and *P. solida*. The 5 species comprised 56%, 25%, 8%, 6% and 4%, respectively, of the 250 colonies. Analyses of data for the most vertical track (track 1) showed significant species-related differences in 4 of the 10 growth parameters. These were effective tissue layer thickness ( $F = 3.32$ ,  $p = 0.01$ ), average annual density ( $F = 5.98$ ,  $p < 0.00$ ), average high density ( $F = 6.26$ ,  $p < 0.00$ ) and average low density ( $F = 5.43$ ,  $p < 0.00$ ). Effective tissue layer thickness was highest in *P. australiensis* ( $0.52 \pm 0.20$ ) and lowest in *P. lobata* ( $0.41 \pm 0.14$ ) (if either of these 2 species were excluded from the analysis there was no significant difference amongst the remaining 4 species). Average annual density (and high and low density) was highest in *P. solida* ( $1.46 \pm 0.21$  g.cm<sup>-3</sup>.yr<sup>-1</sup>) and lowest in *P. mayeri* ( $1.21 \pm 0.14$  g.cm<sup>-3</sup>.yr<sup>-1</sup>). If *P. solida* was removed from the analyses there was no significant difference in average density amongst the remaining four species but if *P. mayeri* was removed there was still a significant difference in average density of the remaining 4 species ( $F = 6.74$ ,  $p < 0.00$ ).

### *Variation around colonies (250 colonies)*

The average height of the 250 colonies was  $360 \pm 94$  mm, average width was  $447 \pm 101$  mm and average height to width ratio was  $0.82 \pm 0.17$ . Thus, on average, these colonies were nearly 20% wider than they were tall. Six of the 10 growth characteristics showed significant differences between the 3 tracks on a coral slice. These were calcification ( $F = 33.49$ ,  $p < 0.00$ ), tissue layer thickness ( $F = 25.19$ ,  $p < 0.00$ ), high-low density ( $F = 6.09$ ,  $p < 0.00$ ), annual extension ( $F = 26.35$ ,  $p < 0.00$ ), high-low extension ( $F = 27.11$ ,  $p < 0.00$ ) and low-high extension ( $F = 15.95$ ,  $p < 0.00$ ). Values for track 1 (most vertical) averaged 15%, 13%, 10%, 16%, 17% and 14%, respectively, higher than values for track 3 (horizontal or near horizontal) for these six growth variables. The other four variables; effective tissue layer thickness, density, high density and low density showed no significant difference with location of the measurement around the coral colonies.

### *Sub-annual variations in extension and density (250 colonies)*

High-low extension ( $6.6 \pm 1.8$  mm.yr $^{-1}$ ) was significantly different to low-high extension ( $6.4 \pm 1.7$  mm.yr $^{-1}$ ) when track 1 data was examined for all 250 colonies ( $t = 2.55$ ,  $p = 0.01$ ). Thus, there was a slight (3%) skewing of the annual density profile. Variations in high and low density were much the same as variations in average density. Similarly, variations in high-low and low-high extension were much the same as variations in average extension. Consequently, these four parameters for the “250 coral collection” are not considered further.

### *Variation from inshore to offshore location (250 colonies)*

Of the 250 colonies, 49% came from inshore locations, 33% from midshelf locations and 18% from offshore locations. When analysed by shelf location (the variable IMO: Inshore, Midshelf or Offshore), 4 of the 6 growth variables showed significant differences. These were effective tissue layer thickness ( $F = 6.99$ ,  $p < 0.00$ ), average density ( $F = 30.86$ ,  $p < 0.00$ ), high-low density ( $F = 11.06$ ,  $p < 0.00$ ) and annual extension ( $F = 9.23$ ,  $p < 0.00$ ). Effective tissue layer was highest at offshore sites ( $0.50 \pm 0.16$  yr) and lowest at inshore sites ( $0.41 \pm 0.16$  yr). Average density was also highest at offshore sites ( $1.40 \pm 0.16$  g.cm $^{-3}$ .yr $^{-1}$ ) and lowest at inshore sites ( $1.22 \pm 0.14$  g.cm $^{-3}$ .yr $^{-1}$ ). High-low density was highest at inshore sites ( $0.13 \pm 0.04$  g.cm $^{-3}$ .yr $^{-1}$ ) and lowest at offshore sites ( $0.11 \pm 0.04$  g.cm $^{-3}$ .yr $^{-1}$ ). Annual extension was highest at inshore sites ( $13.7 \pm 3.5$  mm.yr $^{-1}$ ) and lowest at offshore sites ( $11.6 \pm 3.0$  mm.yr $^{-1}$ ). There was no significant difference in calcification or tissue layer thickness with inshore to offshore location.

#### *Variation from north to south location on the GBR (250 colonies)*

The six growth characteristics were averaged for nine latitude bands between 12-13°S and 21-22°S (no data were available for 19-20°S; Fig. 10). All six variables showed significant differences with latitude: tissue layer thickness ( $F = 5.23, p < 0.00$ ), effective tissue layer thickness ( $F = 6.28, p < 0.00$ ), average density ( $F = 11.15, p < 0.00$ ), high-low density ( $F = 7.10, p < 0.00$ ), annual extension ( $F = 10.97, p < 0.00$ ) and calcification ( $F = 14.11, p < 0.00$ ). Tissue layer thickness, effective tissue layer thickness and average density were all highest in the central GBR, 18-19°S (Fig. 10a, b & c). Annual extension and calcification were both lowest in the southern GBR (Fig. 10e and f).

#### *Relationships between growth variables (250 colonies)*

Interrelationships between growth variables were examined by correlating values for the six growth parameters for all 250 colonies together with the latitude, distance offshore and height of colony (Table 5).

Tissue layer thickness was significantly, though weakly, correlated with calcification and colony height. Inverse correlations of tissue layer thickness with latitude and distance offshore were not significant when allowance was made (using partial correlations) for the high correlation between latitude and distance (ie colonies from further south tended to have been collected further offshore).

Effective tissue layer thickness was significantly correlated with average density and significantly inversely correlated with annual density range, annual extension and calcification. Allowing for the correlation between distance and latitude, effective tissue layer thickness was significantly, though weakly, correlated with distance offshore.

Average density was significantly inversely correlated with annual density range and annual extension. Average density was not significantly correlated with calcification. Allowing for the correlation between latitude and distance offshore, average density was significantly inversely correlated with latitude (ie, density decreased with increasing latitude) and directly correlated with distance from shore (ie, density increased with distance offshore).

The annual density range was significantly correlated with annual extension, calcification and height of the colony (there is greater scope for variation in density in bigger colonies). Allowing for the correlation between latitude and distance, the annual density range

significantly increased with increasing latitude and significantly decreased with distance from shore.

Annual extension significantly increased with colony height and, allowing for the correlation between distance and latitude, decreased significantly with distance from shore. Annual calcification also significantly increased with colony height and decreased significantly with latitude south and distance from shore.

#### Average growth characteristics of 357 Porites colonies from Misima Island to One-Tree Island

##### *Variation with species (357 colonies)*

Five species of *Porites* were represented in the 357 colonies; *P. lobata*, *P. lutea*, *P. australiensis*, *P. mayeri* and *P. solida*. The 5 species comprised 51%, 29%, 9%, 7% and 4%, respectively, of the 357 colonies. Analyses of data for the most vertical track (track 1) showed significant species-related differences in 3 of the 10 growth parameters. These were average annual density ( $F = 4.78$ ,  $p < 0.00$ ), average high density ( $F = 5.15$ ,  $p < 0.00$ ) and average low density ( $F = 4.35$ ,  $p < 0.00$ ). Average annual (and high and low density) was highest in *P. solida* ( $1.46 \pm 0.20 \text{ g.cm}^{-3}.\text{yr}^{-1}$ ) and lowest in *P. mayeri* ( $1.24 \pm 0.13 \text{ g.cm}^{-3}.\text{yr}^{-1}$ ). If *P. solida* was removed from the analysis there was no significant difference in the average density of the remaining 4 species but if *P. mayeri* was removed there was still a significant difference in average density of the remaining 4 species ( $F = 4.732$ ,  $p < 0.00$ ).

##### *Sub-annual variations in extension and density (375 colonies)*

High-low extension ( $6.4 \pm 2.0 \text{ mm.yr}^{-1}$ ) was significantly different to low-high extension ( $6.2 \pm 1.9 \text{ mm.yr}^{-1}$ ) when track 1 data was examined for all 357 colonies ( $t = 2.69$ ,  $p = 0.01$ ). Thus, there was a slight (3%) skewing of the annual density profile. Variations in high-low extension and low-high extension were much the same as variations in average extension. Similarly, variations in high and low density were much the same as variations in average density. Consequently, these four parameters for the “357 colony collection” are not considered further .

##### *Variation from inshore to offshore location (357 colonies)*

Of the 357 colonies, 61% came from inshore locations, 23% from midshelf locations and 16% from offshore locations. When analysed by shelf location (IMO) all six growth variables showed significant differences. Tissue thickness ( $F = 11.02$ ,  $p < 0.00$ ) was highest midshelf and lowest inshore. Effective tissue layer thickness ( $F = 39.29$ ,  $p < 0.00$ ) and average density ( $F = 34.56$ ,  $p < 0.00$ ) were highest offshore and lowest inshore. High-low density ( $F = 4.70$ ,  $p$

$= 0.01$ ) was lowest midshelf and of similar magnitude inshore and offshore. Annual extension ( $F = 18.56, p < 0.00$ ) and calcification ( $F = 7.48, p < 0.00$ ) were both highest inshore and lowest offshore.

#### *Variation from north to south location (357 colonies)*

The six growth characteristics for the 357 coral colonies were averaged for 11 latitude bands between 10-11°S and 23-24°S – no data were available for 11-12°S, 19-20°S and 22-23°S. All six growth variables (Table 6) showed significant differences with latitudinal location: tissue layer thickness ( $F = 16.62, p < 0.00$ ), effective tissue layer thickness ( $F = 31.58, p < 0.00$ ), average density ( $F = 16.96, p < 0.00$ ), high-low density ( $F = 7.45, p < 0.00$ ), annual extension ( $F = 17.16, p < 0.00$ ), and annual calcification ( $F = 19.03, p < 0.00$ ). Effective tissue layer thickness tended to be higher in the more southerly sites while annual extension and calcification tended to be lower in the more southerly sites.

#### *Relationships between growth variables (357 colonies)*

Interrelationships between growth variables were examined by correlating values for the six growth parameters for all 357 colonies together with the latitude, distance offshore and height of colony (Table 7). The majority of the significant relationships identified for the 250 GBR coral colonies (Table 5) were evident in the 357 coral colonies. Exceptions were: 1) tissue layer thickness which increased significantly with latitude and decreased significantly with distance offshore in the 357 colonies, even allowing for the correlation of latitude with distance offshore and 2) effective tissue layer thickness which increased significantly with latitude, again allowing for the correlation of latitude with distance offshore.

#### Average growth characteristics of 35 coral cores

Average growth characteristics, for the common period 1934 to 1982, for the 35 long coral cores are summarized in Table 4. The coral cores were not identified to species and only a single track was measured along each coral core. Therefore, it was not possible to analyse coral core growth characteristics for variation with species or location around colony.

The coral cores averaged  $3.7 \pm 1.6$  m in height whereas the coral colonies averaged  $0.3 \pm 0.1$  m in height. The average growth characteristics obtained from the 35 coral cores were different to those obtained from the 357 coral colonies (compare overall means and sds in Tables 4 and 6). Three of the 6 growth characteristics were significantly higher in the coral cores than in the coral colonies: tissue layer thickness ( $t = 10.03, p < 0.00$ ), effective tissue layer thickness ( $t = 2.69, p = 0.01$ ) and extension ( $t = 3.83, p < 0.00$ ). Average density ( $t = -5.00, p < 0.00$ ) was significantly less in the coral cores than in the coral colonies. The annual density range was

the same for both coral cores and colonies and there was no significant difference in calcification between the coral cores and the coral colonies.

#### *Sub-annual variations in extension and density (35 cores)*

High-low extension ( $7.6 \pm 1.7$  mm.yr $^{-1}$ ) was significantly different to low-high extension ( $7.2 \pm 1.6$  mm.yr $^{-1}$ ) for the 35 coral cores ( $t = 2.80, p = 0.01$ ). Thus, there was a slight (5%) skewing of the annual density profile. Variations in high-low extension and low-high extension were much the same as variations in average extension. Similarly, variations of high and low density were much the same as variations in average density. Consequently, these 4 parameters for the coral core collection are not considered further.

#### *Variation from inshore to offshore location (35 cores)*

Of the 35 coral cores, 60% came from inshore sites, 26% from midshelf sites and 14% from offshore sites. None of the 6 growth parameters in the 35 coral cores showed significant differences with inshore-offshore location.

#### *Variation from north to south location on the GBR (35 cores)*

Because of the uneven latitudinal distribution of the coral cores (see Fig. 2), the data were grouped into 3 latitudinal bands: 9-17°S (9 cores), 17-20°S (16 cores) and 20-24°S (10 cores). Three of the 6 growth parameters showed significant differences between these 3 latitudinal bands: effective tissue layer thickness was lowest in the north and highest in the south ( $F = 4.15, p = 0.03$ ); annual extension ( $F = 4.34, p = 0.02$ ) and calcification ( $F = 4.83, p = 0.02$ ) were both highest in the north and lowest in the south. There was no significant difference in tissue layer thickness, average density or high-low density with latitude.

#### *Relationships between growth variables (35 cores)*

Interrelationships between growth variables were examined by correlating values for the six growth parameters for all 35 cores, together with latitude, distance offshore and height of colony (Table 8). Comparisons of these correlations with those for the 250 coral colonies (Table 5) and 357 coral colonies (Table 7) showed the following relationships to be consistent amongst the 3 data-sets: high-low density was significantly correlated with annual extension and calcification; annual extension significantly decreased with distance offshore; and annual calcification significantly decreased with distance offshore and increasing latitude.

### Relationships between coral growth characteristics and environmental gradients

Average coral calcification and extension both showed clear latitudinal gradients, with lowest values observed in more southerly latitudes of the GBR region (see Tables 5, 6, and 7). Both average annual SST and solar radiation decreased with increasing latitude (Fig. 5b and 6b). Based on  $2^{\circ}$  latitude data (only 7 data pairs, solar radiation averages were only available at this resolution), the correlation between calcification and SST was 0.86 (significant at 5% level) and between calcification and solar radiation was -0.62 (not significant); the correlation between extension and SST was 0.81 (significant at 5% level) and between extension and solar radiation was -0.65 (not significant). Solar radiation could not be analysed at the  $1^{\circ}$  latitude scale. Based on  $1^{\circ}$  latitude data (11 data pairs), the correlation between SST and calcification was 0.93 and between SST and extension was 0.89 (both coefficients significant at 5% level, see Fig. 11). There were no significant correlations between coral growth parameters and other environmental variables such as river flow and tropical cyclone activity.

## SUMMARY

Average growth characteristics of the major reef-building coral, *Porites*, have been obtained for 357 coral colonies and 35 long coral cores from the region of the Great Barrier Reef (GBR). Annual growth characteristics were obtained from the annual density banding pattern which is characteristic of massive coral species. We provide (new) baseline data for average growth characteristics and range in growth characteristics for *Porites* through  $14^{\circ}$  ( $\sim 1,500$  km) of latitude along the GBR and from the coast to  $\sim 200$  km offshore in colonies ranging in size from 0.1-8.0 m in height. This is by far the most comprehensive database of coral growth characteristics so far published.

The database allows testing for a) systematic differences in various growth characteristics of corals growing at different locations in the GBR region, b) relationships amongst coral growth characteristics, and c) possible linkages between coral growth characteristics and environmental gradients. In earlier studies we examined components of this database for evidence of inshore-to-offshore gradients in growth characteristics for the central GBR (Lough & Barnes, 1992), long-term (several centuries) variations in growth characteristics (Lough & Barnes, 1997) and changes in growth characteristics with changes in environment (Lough *et al.*, 1995; Barnes & Lough, in press).

In this report we present new analyses of the entire database (rather than components of the database). Growth characteristics are analysed in three groups: a) 250 colonies from the GBR all collected from similar reef environments by our group for the present study (colony height averaging 360 mm and ranging from 170-700 mm), b) 357 colonies from Misima Island and Ashmore Reef to the north of the GBR to One-Tree Island to the south of the GBR. This set of colonies comprises the 250 colonies from the GBR, supplemented by colonies not collected by our group from Misima Island, Ashmore Reef and One-Tree Island. Colonies from Misima Island and colonies from One-Tree Island were different in size and age to colonies from the various GBR transects (Table 3), and c) 35 long coral cores from large colonies of *Porites* from the GBR. The coral cores came from colonies between 1.6-8.0 m in height.

The major findings from analyses of these data are as follows:

- ?? Tissue layer thickness, effective tissue layer thickness and annual extension were significantly higher in the coral cores (1.6-8 m in height) than in the coral colonies (0.1-0.7 m in height) by 33%, 17% and 16%, respectively. Average skeletal density was significantly less in the coral cores than in the coral colonies by 11%. There was no significant difference in the annual density range or average calcification between the coral cores and coral colonies.
- ?? The 357 coral colonies comprised 5 species: *P. lobata* (51%), *P. lutea* (29%), *P. australiensis* (9%), *P. mayeri* (7%) and *P. solida* (4%). Coral cores were not identified to species. The only coral growth parameter to show a significant difference with species was average density. This was significantly higher in *P. solida* compared with the other 4 species.
- ?? Growth parameters for the 250 colonies from the GBR were examined along 3 densitometer tracks around the coral colony: 2 tracks nearly vertical to the major growth axis and one track near horizontal to the major growth axis. Tissue layer thickness, high-low density, annual extension and calcification varied significantly with location of track around colony. Average values for the most vertical track were, respectively, 13%, 10%, 16% and 15% higher than for the near horizontal track. There was no significant variation in effective tissue layer thickness or average skeletal density with location around the coral colony. The 250 coral colonies averaged 20% wider than they were tall.
- ?? The annual density profile was significantly skewed in all data sets with high-low extension (growth from winter to summer) averaging 3-5% greater than low-high extension (growth from summer to winter).

- ?? 61% of the coral colonies (60% coral cores) came from inshore reef sites, 23% (26% coral cores) came from midshelf sites and 16% (14% coral cores) came from offshore reef sites. No significant differences were found with shelf location for growth characteristics obtained from the coral cores. Three growth parameters showed the same significant differences between shelf location when the 250 colony and 357 colony data sets were examined: effective tissue layer thickness and average skeletal density were highest at offshore sites and lowest at inshore sites and extension was highest at inshore sites and lowest at offshore sites.
- ?? Growth characteristics were compared between 9 latitude bands for the 250 colonies, 11 latitude bands for the 357 colonies and 3 latitude bands for the 35 coral cores. Three growth parameters showed significant and similar differences in the three data sets with north to south location: effective tissue layer thickness was highest in the southern GBR and average extension and calcification were both lowest in the southern GBR.
- ?? Cross-correlations between the different growth variables showed a) the following relationships to be significant and of similar magnitude in the 2 coral colony data sets: tissue layer thickness was correlated with calcification, effective tissue layer thickness was correlated with average density, and average density was inversely correlated with annual density range and extension, and b) the following relationships to be significant and of similar magnitude in the 2 coral colony and coral core data sets: the annual density range was inversely correlated with effective tissue layer thickness and directly correlated with both extension and calcification.
- ?? Both linear extension and calcification decreased with increasing latitude. Based on the 357 colony data, extension and calcification were significantly correlated with average annual sea surface temperature. Extension and calcification were not correlated with average incoming solar radiation, rainfall, tropical cyclone activity or river flow.

## DISCUSSION

Tissue layer thickness, effective tissue layer thickness and annual extension were all significantly higher and annual density significantly lower in the larger (=older) colonies compared with the smaller (=younger) colonies. There were no significant differences in average calcification or annual density range with colony age and size. These results are based on comparisons of average colony growth characteristics for the most recent (1934-1982) part of the long coral cores, the oldest of which are ~4-500 years old. Increase in tissue layer thickness with colony size has been reported previously (Barnes & Lough, 1992). We have also previously noted, from examination of the 35 long coral cores (Lough & Barnes,

1997), a tendency for the oldest parts of the very old colonies (equivalent to the coral colonies) to have higher density and lower extension than the younger parts of the same colonies. These changes over time in extension and density appeared to compensate each other and there was no overall change in calcification with colony age. Evidence presented here supports this conclusion. There was a significant increase in extension and decrease in density with increasing colony size and age. The width of annual rings in trees also shows a systematic change with tree age (Fritts, 1976). The width of the annual ring tends to be highest in young trees and decreases in size with increase in tree age. As a consequence, it is necessary for dendroclimatologists to remove this “growth curve” before attempting to interpret any environmental information contained in the tree rings series. This procedure also limits the amount of century-time scale variability that can be obtained from tree-ring reconstructions (eg Cook *et al.*, 1995). Evidence, presented here, of age-growth trends has implications for the measurement and interpretation of long-term environmental changes from records contained in long-lived colonies of *Porites*. First, in assessing long-term changes in coral growth characteristics and possible environmental changes, calcification rate should be used rather than skeletal density or extension rate. Second, sub-sampling of “annual” growth increments for inclusive records (eg O<sup>18</sup>, Sr/Ca) should take into account different extension rates between the younger and older part of a colony.

Average skeletal density was the only coral growth characteristic to show a significant difference amongst the 5 species of *Porites* examined. Skeletal density was significantly higher in *P. solida* compared with the other 4 species. There was no significant difference in tissue layer thickness or effective tissue layer thickness between species. Consequently, differences in density between species probably result from species-related differences in the thickness of the initial skeletal “scaffolding” and in the amount of thickening applied to that scaffolding through the depth of the tissue layer (see Barnes & Lough, 1993; Taylor *et al.*, 1993). This suggests that species may be a factor affecting reconstruction of environmental information from stable isotopes and trace inclusions in *P. solida* (see Taylor *et al.*, 1995; Barnes *et al.*, 1995) and this species of *Porites* should be used with caution. This finding emphasises the need to identify massive *Porites* to species level when using them for environmental reconstructions.

Tissue layer thickness, high-low density, annual extension and calcification were significantly higher at the top than at the side of the 250 coral colonies (13%, 10%, 16%, 15%, respectively). These colonies were generally hemispherical in shape and averaged 20% wider than they were tall. As skeletal density did not vary from tops to sides of colonies while annual extension and calcification decreased by equivalent amounts, the decrease in

calcification was mostly due to a decrease in annual extension. Effective tissue thickness is the only factor that might modify this complete linkage of annual extension rate with calcification rate. A differing residence time of tissue over skeletal elements could alter the estimated calcification rate in a fashion unconnected with extension rate. Tissue layer thickness did decrease from tops to sides of colonies, as reported previously (Barnes & Lough, 1992). However, a concomitant decrease in extension rates meant that effective tissue layer thickness was not significantly different between tops and sides of colonies. Thus, there was no significant change around the colonies in the time that tissue resided over skeletal elements. It does then seem that the decrease in calcification from tops to sides of colonies is mostly due to a decrease in extension. It seems probable that variation in light between tops and sides of colonies is the only factor that could produce such a systematic trend across many colonies from many locations. Thus, light may be a major factor influencing extension in *Porites*. Such influence may not arise from the well-recognised linkage between light intensity and calcification rate. Indeed, calcification in these colonies from very shallow water is not likely to have been light-limited since photosynthesis would have been saturated through most of the day (see Lough & Barnes, 1997). The link between extension and light seen here may have simply resulted because the colonies tend to distribute their resources so that they grow more towards the light (eg, Kawaguti, 1937a,b; see also Yonge, 1963).

The annual density profile was significantly skewed with  $H-L_{dist}$  (? extension from winter to summer) averaging 35% higher than  $L-H_{dist}$  (? extension from summer to winter). On average, peaks in SST lagged 2.5 months behind peaks in solar radiation at all latitudes. However, times between summer peaks and winter troughs, and winter troughs and summer peaks for SST and solar radiation differed with latitude:

- ?? from 10-14°S, SST and solar radiation maxima to minima were 5 months and 4 months, respectively,
- ?? from 16-18°S, SST and solar radiation maxima to minima were 7 months and 4 months, respectively,
- ?? from 18-20°S, SST and solar radiation maxima to minima were 7 months and 5 months, respectively,
- ?? south of 20°S, SST and solar radiation maxima to minima were both 6 months.

Thus, the skewness in temperature and solar radiation were considerably greater than the skewness in coral density profiles. This suggests that neither SST nor solar radiation are the sole driving force for coral skeletal growth. Rather, it suggests that both factors play a role in

the formation of coral density bands. More accurate intra-annual timing of density peaks and troughs is required to resolve this problem.

Significant cross-shelf trends in *Porites* growth characteristics were only found for the most northerly (~ 12.50°S) and central (~ 18.30°S) transects (Lough & Barnes, 1992). Extension was found to decrease and density increase with distance offshore in these two transects. Only in the central transect was there a significant decrease in average calcification with distance offshore. Analyses presented here show no significant differences with distance offshore for the long coral cores but for the coral colonies, effective tissue layer thickness and average density were significantly higher offshore than at inshore sites and average extension was significantly lower at offshore sites than at inshore sites. The most likely cause of inshore-offshore gradients in coral growth characteristics is the availability of nutrients which will be lowest at offshore reefs. In the offshore reefs of the southern GBR there is evidence (M. Furnas, AIMS pers. comm.) of large planktonic populations and the reefs appear most similar to the mid-shelf reefs of lower latitudes. Nutrients limit tissue growth which limits extension and in turn causes higher skeletal density. Wave energy may also be a factor in inshore-offshore trends in growth characteristics.

Previous studies (Grigg, 1982a,b; Isdale, 1983; Lough & Barnes, 1997; submitted) have suggested changes in *Porites* growth characteristics with latitude. Results presented here support these findings with effective tissue layer thickness being highest and average extension and calcification being lowest in colonies from the southern GBR. Inter-annual variations of calcification in *Porites* are significantly related with sea surface temperature but not with light (Lough & Barnes, 1997). The north-south variations in average annual calcification and annual extension reported here were found to be significantly correlated with latitudinal variations in average annual sea surface temperatures. Thus, sea surface temperature appears to be the primary forcing factor for average and inter-annual variations in extension and calcification in *Porites*. Using the relationship between average annual SST and coral calcification in space presented in this report (Fig. 11a) a 1°C increase in SST would lead to an increase in calcification of 0.34 g.cm<sup>-2</sup>.yr<sup>-1</sup>. Using the relationship between annual SST and coral calcification in time published earlier (Fig. 10 in Lough & Barnes, 1997) a 1°C increase in SST would lead to an increase in calcification of 0.32 g.cm<sup>-2</sup>.yr<sup>-1</sup>. Thus, SST appears to be a primary control of calcification in *Porites* in both space and time.

Examination of the interrelationships between the coral growth variables showed that annual calcification tended to increase with increased thickness of the tissue layer and that this was most evident at offshore sites. However, variations in calcification were almost entirely

associated with variations in extension and, consequently, it may not be appropriate to link tissue thickness with calcification (see below). It should be noted that calcification is expressed here per unit surface area of colony rather than per unit area of all skeletal elements covered by tissue. This has been one common way for standardising calcification (another is to standardise by tissue protein, which is probably a better measure of skeleton available for new growth). It may be that some of the problems encountered in standardising experimental measurements of calcification (Barnes & Crossland, 1977; Crossland & Barnes, 1977) may have arisen because the thickness of the tissue layer has not previously been considered an important parameter in corals (see Barnes & Lough, 1992).

Density was correlated with effective tissue layer thickness but not with tissue layer thickness. This fits well with the concept that density variations in *Porites* result from variations in the amount of thickening applied to skeletal elements over the time that those elements were covered by tissue (Barnes & Lough, 1993; Taylor *et al.*, 1993).

Annual extension varied significantly and inversely with average skeletal density. A weak, inverse relationship between annual extension and density has been previously noted in *Porites* (Scoffin *et al.*, 1992; Lough & Barnes, 1997). This accords with the notion that variations in density result from variations in the thickening applied to the initial deposits responsible for extension (Barnes & Lough, 1993) because a higher extension rate might allow less time for thickening.

Data presented here demonstrate north-south gradients in coral growth on the GBR that accord with previous work. Until the early 1980's most work concentrated upon such north-south variations in coral performance and ecology, and in the performance and ecology of whole reefs and their fauna and flora. It then became apparent that there exist on the GBR east-west (inshore-offshore) gradients over a few 10s of km that are more marked than north-south gradients over several 100s of km (eg Done, 1982). Work presented here confirms that there are marked inshore-offshore gradients in coral growth parameters in regions where shelf-width and reef structure are likely to set up environmental gradients between the coast and the Coral Sea. However, the results suggest that such inshore-offshore gradients may not be as simple and clear-cut as they have previously been thought. Measurements of coral growth performance over 10s of years from annual banding patterns are one simple way to identify and map environmental gradients. It seems likely that we do not yet have sufficient coral performance data to understand why and which environmental factors are setting up and maintaining the inshore-offshore gradients that have importance to corals and coral reefs. It is however apparent that we have gained much better knowledge of growth mechanisms in

*Porites*. We are now much better able to link variations in growth parameters one with another and we are beginning to recognise how variation in growth parameters links with variation in environmental conditions.

## **ACKNOWLEDGEMENTS**

The long coral cores used in this work were obtained by Dr P.J. Isdale of AIMS. We thank Misima Mines Pty Ltd for allowing us to publish the growth information obtained for *Porites* colonies collected as part of their Environmental Monitoring Program. We thank Rob White (formerly of Misima Mines Pty Ltd) for collecting the colonies at Misima Island. We thank Andy Steven (formerly of Great Barrier Reef Marine Park Authority) for making available to us his *Porites* data from One-Tree Island. Ray Taylor engaged us in thoughtful discussion of many aspects of the data presented here. He also provided useful comments upon the final drafts of this report.

## **APPENDIX A: Collection details for coral colonies**

Average growth data are presented for 365 coral colonies from 31 reef sites on the Great Barrier Reef, the fringing reef of the southern coast of Misima Island, PNG and the Huon Peninsular, PNG. These data come from 9 collections of *Porites* coral colonies. A brief description of these 9 collections follows:

### *Ashmore Reef*

8 *Porites* colonies were collected from Ashmore Reef (an offshore reef, 195 km from Papua New Guinea) in December 1989 by Bruce Chalker (then at AIMS). Colonies were collected on the lagoon side of the southwest end of the reef in water depths of 3-6m. Growth data were extracted for 4 of the colonies for the common period 1976-1988. This collection resulted from opportunistic sampling during an AIMS' research cruise.

### *Northern Great Barrier Reef*

80 colonies of *Porites* were collected from 3 inshore, 2 mid-shelf and 2 offshore reefs lying between 12.50°S and 13.33°S in July 1990 by Monty Devereux (AIMS). Colonies, between 0.2m and 0.5m in height, were collected from depths of 3-5 m relative to mean low water spring tide levels from similar environments in deeper water on reef flats. These reefs formed 2 inshore-offshore transects separated by ~85km in the northern Great Barrier Reef (GBR). The more southerly of these transects was about 140km north of Princess Charlotte Bay. It was centred about 13.27°S and comprised Night Island, 13-055 Reef and 13-050 Reef. The other transect was centred about 12.52°S and comprised Portland Roads, Rocky Island, Eel Reef and Lagoon Reef. The GBR is narrow in this region and the shelf-edge reef sites (Lagoon and 13-050 Reefs) were only about 40km from the coast. The 3 inshore sites (Rocky and Night Island, and Portland Roads) were all reefs fringing islands. Colonies were collected from the north-west ends of these reefs, which were sheltered from the south-east trade winds. Colonies were collected at the southern end of mid-shelf and offshore reefs, towards the rear of the reef flat. These reefs are subject to a tidal range of ~2-3m. This collection was made to examine growth characteristics of *Porites* along an inshore to offshore transect in the northern GBR. Growth data were extracted for 69 of the colonies for the common period 1977-1989.

### *Cairns-Cape Melville*

97 *Porites* colonies were collected from 12 inshore to mid-shelf reef sites lying along a north (Cape Melville, Tydeman Reef~14.00°S) to south (near Cairns, Double Island ~16.73°S) transect in May 1992 by Monty Devereux (AIMS). Most colonies were collected from the lee side of the islands (NW to SW), reef flats or just into the lagoon areas from 3-5m water depths. This collection was made to examine *Porites* growth characteristics in nearshore environments between Cairns and Cape Melville.

### *Mission Beach*

6 *Porites* colonies were collected by Ted Daniel (then at AIMS) from Stephens and Bedarra Islands in June 1988 and 21 colonies (by Monty Devereux, AIMS) in April, 1989. Colonies were collected from sheltered parts (NW-SW) of reef flat areas in the lee of the islands from water depths of 2-3m at Stephens Island and 2-4m at Bedarra Island. Growth data were extracted for 21 of the colonies for the common period (1979-1988 for colonies collected in April 1989 and 1978-1987 for colonies collected in June 1988). This collection was made to examine *Porites* growth characteristics adjacent to the wet tropical coast of north Queensland.

### *Central Great Barrier Reef*

40 colonies of *Porites* were collected from an inshore to mid-shelf to offshore transect between 18.16°S and 18.49°S in November 1987 by Monty Devereux (AIMS). The inshore site was Pandora Reef, the mid-shelf site was Rib Reef and the offshore site was Myrmidon Reef. The GBR is fairly wide in this central section, with the offshore reef located 110km from the coast. Colonies, between 0.2m and 0.5m in height, were collected from depths of 3-5 m relative to mean low water spring tide levels from similar environments in deeper water on reef flats. These sites were located on the south-southwest side of the reefs. These reefs are subject to a tidal range of ~2-3m. Growth data were

extracted for 25 of the colonies for the common period 1974-1986. This collection was made to examine growth characteristics of *Porites* along an inshore to offshore transect in the central GBR. (see Lough & Barnes, 1992).

#### *Southern Great Barrier Reef*

60 colonies of *Porites* were collected from 2 inshore, 1 mid-shelf and 2 offshore reefs lying between 20.27°S and 21.39°S in May 1989 by Monty Devereux (AIMS). These reefs formed 2 inshore-offshore transects, separated by ~130km, in the southern GBR. Colonies were collected from Shaw and Middle Percy Islands (inshore, Credlin and 21-141 Reefs (mid-shelf) and 20-200 Reef (offshore). We have classified Middle Percy Island as an inshore site, although it is 80km offshore. This is because of an extensive array of shoals and mud which separates it from the mainland. Charts and aerial photographs showed no reefs closer inshore at this point. The GBR is wide in this southern region and the site furthermost offshore (20-200 Reef) was 174km from the coast. One transect, centred about 20.30°S, comprised Shaw Island, Credlin Reef and 20-200 Reef. The second transect, centred about 21.35°S, comprised Middle Percy Island and 21-141 Reef. There was no shelf-edge site in this second, most southerly transect. These southerly reefs are subject to a tidal range of ~5-6m. Colonies, between 0.2m and 0.5m in height, were collected from depths of 3-5 m relative to mean low water spring tide levels from similar environments in deeper water on reef flats. Corals were collected from fringing reefs in the lee of islands. Colonies were collected from the rear of the reef flat at the southern end of mid-shelf and offshore reefs. Growth data were extracted for 45 of the colonies for the common period 1972-1988. This collection was made to examine growth characteristics of *Porites* along an inshore to offshore transect in the southern GBR.

#### *One-Tree Island*

13 small colonies (0.09 to 0.16m in height) of *Porites lobata* were collected by Andy Steven (then at Great Barrier Reef Marine Park Authority) as part of his Ph.D. research during the ENCORE experiment at One Tree Island in the southern GBR. Three of the colonies were collected in December, 1995 and the remainder in March 1996. Growth data were extracted for 10 of the colonies for the common period 1985-1995 (colonies collected in March 1996) and 1984-1994 (for colonies collected in December 1995). (see Steven, to be submitted).

#### *Misima Island, PNG*

104 colonies of *Porites*, 0.2m-0.4m in height, were collected from the fringing reef at Misima Island, PNG (10.6°S, 152.8°E) in March 1994 by Rob White (Misima Mines Pty Ltd). Misima Island is a small (230km<sup>2</sup>), mountainous island lying to the southeast of Papua New Guinea. The construction in 1988 of an open cut gold mine and ore-processing facility resulted in disturbance of the adjacent fringing reef, mostly because of huge increases in sedimentation. This collection of *Porites* colonies was made (as part of the Environmental Monitoring Program of Misima Mines Pty Ltd) to examine whether growth characteristics of this major reef-building coral were altered by the mining activities. Colonies were collected from 10 transects (T1-T10), established by NSR Environmental Consultants Pty Ltd. They defined zones of expected “severe”, “transitional” and “minor” impact, and control zones (no impact) on the fringing reef to either side of the mine site. Colonies were collected from water depths of 6-8m. Growth data were extracted for 93 of the colonies for the common period 1984-1993. Seven of these colonies (from “severe” impacts transect T4) were dead at the time of collection. (see Lough *et al.*, 1995; Barnes & Lough, in press).

#### *Huon Peninsula, PNG*

John Pandolfi (then at AIMS) collected 9 colonies of *Porites* in October 1993 from the Huon Peninsula, PNG. Two of these colonies were living. The remaining seven colonies were from a reef uplifted *in situ* as a result of an earthquake and estimated to be 6-9,000 years old. Growth data were extracted for 8 of the colonies. These corals were collected to examine whether growth characteristics could be extracted from very old *Porites* colonies. The colonies were small in size but John Pandolfi reported much larger colonies (1-2m in height) from the site.

## APPENDIX B: Average annual growth characteristics for coral colonies

The following tables contain average coral growth characteristics for each track and coral colony analysed. \* indicates category 1 dating; all other samples are category 2 dating. Annual data are averaged over the indicated base periods. The following variables are listed:

Height:	of coral colony (mm)
Width:	of coral colony (mm)
H/W ratio:	Ratio of height to width (indicative of colony shape eg hemispherical, columnar etc)
Species:	<i>Porites</i> species where:
	lob = <i>P. lobata</i>
	lut = <i>P. lutea</i>
	sol = <i>P. solida</i>
	may = <i>P. mayeri</i>
	aus = <i>P. australiensis</i>
Year:	earliest dated year for track 1 series
	<i>TTL</i> : depth of living tissue layer at outer surface of colony (mm)
<i>ETTL</i> :	effective tissue layer thickness; ratio of <i>TTL</i> to average extension, $H-H_{dis}$ (yr)
$A_{den}$ :	annual average density ( $\text{g.cm}^{-3}.\text{yr}^{-1}$ )
$H_{den}$ :	average high density ( $\text{g.cm}^{-3}.\text{yr}^{-1}$ )
$L_{den}$ :	average low density ( $\text{g.cm}^{-3}.\text{yr}^{-1}$ )
$H-L_{den}$ :	average annual density range; high minus low density ( $\text{g.cm}^{-3}.\text{yr}^{-1}$ )
$H-H_{dis}$ :	annual extension rate measured as distance between successive high density maxima ( $\text{mm.yr}^{-1}$ )
$H-L_{dis}$ :	average extension from high density maximum to low density minimum ( $\text{mm.yr}^{-1}$ )
$L-H_{dis}$ :	average extension from low density minimum to high density maximum ( $\text{mm.yr}^{-1}$ )
<i>CALCN</i> :	annual calcification rate or mass of $\text{CaCO}_3$ deposited per unit area per year ( $\text{g.cm}^{-2}.\text{yr}^{-1}$ ): the product of average annual density and annual extension

**Table B1:** Ashmore Reef, 10.25°S, 144.50°E: Average annual coral growth characteristics ( $\pm$  sd), 1976-1988 base period. \* indicates category 1 dating; Year is earliest dated year for track 1.
